Background: Spontaneous pneumothorax as a complication of COVID-19 pneumonia is either uncommon or under-reported. The exact incidence and risk factors are still unknown. The objective of this study is to highlight an important complication, its incidence and explore the predisposing risk factors. **Methods:** We performed a retrospective review of COVID-19 pneumonia cases admitted to our hospital between February 2021 and June 2021. Data on their demographics, pre-existing risk factors, laboratory workup, imaging, treatment and clinical outcomes were gathered. **Results:** One thousand eight hundred and twenty-five patients have admitted to our institution between February 2021 and June 2021 with COVID-19 infection. 11 patients developed a pneumothorax (0.6%). 6 out of the 11 cases were patients who required mechanical ventilation (54.5%). All of these patients underwent chest tube insertion. Baseline imaging of these patients showed ground-glass opacities (GGO) and consolidation. 8 of the 11 patients succumbed to the disease (72.7%). **Conclusion:** In patients admitted with COVID-19 pneumonia and developing sudden respiratory compromise, pneumothorax is an important complication to be considered. Prompt identification of this complication and timely intervention is necessary to reduce morbidity and mortality. Low tidal volume lung-protective ventilation and the use of non-invasive ventilation for oxygenation remain the cornerstone in the management of COVID pneumonia. It significantly decreases iatrogenic complications like VILI (ventilator-induced lung injury) and P-SILI (patient self-inflicted lung injury.

Introduction

Coronavirus is a family of an RNA virus and the disease is caused by SARS-CoV-2 capturing the world by its jugular. COVID-19 was declared a global health emergency by the WHO as of January 30, 2020. [1,2]. Pneumothorax is often a late manifestation and complication that presents during the treatment of COVID-19 pneumonia [3,4,5]. Pneumothorax increases the risk of mortality when undiagnosed or untreated. [6]. In a study published by Yang and colleagues in 92 deceased COVID-19 patients, one (1.1%) had a pneumothorax and died as a result of it 5 days after the initial presentation. [7]. Pneumothorax has also been linked to poor prognosis in patients infected with the acute Middle East respiratory syndrome coronavirus (MERS-CoV). [8]. Both pneumothorax and pneumomediastinum are known complications of mechanical ventilation. [3,9]. Nonetheless, even without barotrauma, pneumothorax, pneumomediastinum, or more rarely both, can be present in COVID-19. [10,11]. In this study, we aim to explore the risk factors and understand the pathophysiology of pneumothorax in COVID-19 pneumonia.

Materials & Methods

A retrospective review of data of patients admitted to our institution with COVID-19 disease between February 2021 and June 2021 was performed. During this period one thousand eight hundred and twenty-five patients were treated in our institution. They were diagnosed via RT-PCR or antigen test. All patients were evaluated with a chest radiograph and CT thorax during the hospital stay. Pneumothorax was confirmed with a chest radiograph. Patients with pneumothorax were reviewed thoroughly. Details regarding risk factors (comorbidities, smoking, BMI, ventilation status and steroid use), laboratory parameters (CRP, LDH, Serum Ferritin, D-Dimer and total counts), imaging findings (chest radiograph, CT severity score and CORADS), treatment modalities and outcome of disease were documented for each patient.

Sample Size: 1825

Sample size equation- Estimation of proportion:

$$n = \frac{Z^{2}_{1-\alpha/2} pq}{(p\varepsilon)^{2}}$$

Where,

P– Anticipated proportion of event

q = 1-p

ε - precision

$Z_{1-\alpha/2}$ - Statistical table values

- **Sampling method:** Convenient sampling.
- **Study design***:* Retrospective Observational study (from hospital records).
- **Study area:** Department of General Surgery and Department of Anesthesiology, MOSC Medical College Hospital, Kolenchery, Ernakulam, Kerala.
- **Study population:** Moderate to Severe COVID positive patients in Kerala.
- **Inclusion criteria:** All patients who got admitted with *Moderate to Severe* COVID-19 infection.
- **Exclusion criteria:** Patients who expired before appropriate evaluation or treatment.
- **Ethical Considerations:** Approval was sought from the institutional ethics committee. Waiver of Informed consent was sought from the IEC.

Results

In our study, it was observed that the mean age of presentation was 51 years of age. The most common presenting symptoms were cough, fever and breathlessness. The average duration of symptoms was 4.9 days. It was noted that none of the patients was vaccinated at the time of presentation. 5 patients who developed pneumothorax were referred cases with severe COVID-19 pneumonia. (Table 1 & 2)

Patients who developed pneumothorax had comorbidities such as diabetes mellitus, hypertension, coronary artery disease, valvular heart disease, BPAD, nephrotic syndrome, COPD and pulmonary tuberculosis. Only one patient had a significant pulmonary disease (COPD, pulmonary tuberculosis) with a history of smoking. 2 patients had a history of intake of steroids. One patient had a BMI of less than 18.5kg/m2 (underweight), 2 patients had a BMI of more than 30kg/m2 (obese) and 8 patients had a BMI of 25-kg/m2 (overweight). (Table 1 & 2)

Table 1: Presenting Symptoms and Vaccination Status.

Sr no	Symptoms	Numbers & percentage	Vaccination status
1	Cough	9(81.8%)	Not vaccinated
2	Fever	7(63.6%)	Not vaccinated
3	Breathlessness	8(72.7%)	Not vaccinated
4	Diarrhoea	2(18.1%)	Not vaccinated
5	Vomiting	1(9.09%)	Not vaccinated
6	Swelling in the neck and chest	1(9.09%)	Not vaccinated

Table 2: Comorbidities and Risk Factors.

Sr No.	Comorbidities/ Risk factors	Numbers and Percentages
1	Diabetes mellitus	7(63.6%)
2	Systemic hypertension	6(54.5%)
3	COPD & Pulmonary edema	1(9.09%)
4	CAD	2(18.18%)
5	Valvular heart disease	1(9.09%)
6	Nephrotic syndrome	1(9.09%)
7	Dyslipidemia	1(9.09%)

The mean serum LDH level was 825 U/L whereas the mean serum Ferritin level was 844.5 mcg/L. The D-Dimer, total counts and CRP levels were noted to be high in patients who developed pneumothorax. 9 patients who developed pneumothorax, had bilateral chest infiltrates on chest radiograph at presentation. CT findings included ground-glass opacities (GGO), consolidation and pneumomediastinum. (Figure 1 & 2).

Figure 1: Chest Xray Showing Left Pneumothorax and Right-Sided Consolidation.

Table 3: Salient Xray and Ct Findings of Patients with Pneumothorax.

Sr No.	Xray Findings	Numbers and Percentages	CT findings	Numbers and Percentages
1	Chest infiltrates	9(81.8%)	Ground glass opacities	8(72.72%)
2	Pneumothorax	2(18.18%)	Consolidation	8(72.72%)
3			Pneumomediastinum	1(9.09%)
4			Pneumothorax	2(18.18%)

CT severity score was more than 12 in all patients with the mean score being 20.

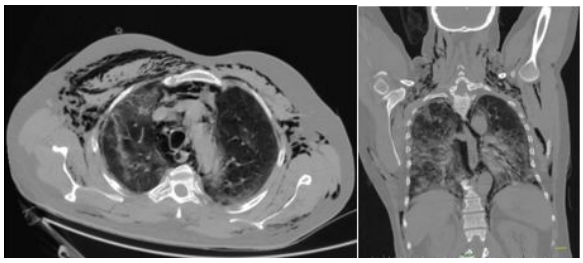

Figure 2: Axial and Coronal Sections of Ct Imaging Showing Ground Glass Opacities, Subcutaneous Emphysema, Pneumomediastinum and Pneumothorax.

The mean time of development of pneumothorax was noted to be 11 days after testing positive for COVID-19 infection. 6 patients who developed pneumothorax had subcutaneous emphysema. All patients underwent intercostal drainage and one patient required multiple same side intercostal drain (ICD) insertions for persistent non-resolving pneumothorax. One patient also underwent prophylactic ICD insertion on the opposite side to decrease the tracking of air from the affected lung. (Table 4).

Table 4: Clinical Features and Icd Details.

Sr no.	Subcutaneous Emphysema	Number and Percentages	ICD position and number	Number and Percentages
1	Present	6(54.54%)	Unilateral	8(72.72%)
2	Absent	5(45.45%)	Bilateral	3(27.27%)
3			Single ICD	8(72.72%)
4			Multiple ICD	3(27.27%)

In our study 11 out of 1825 patients developed a pneumothorax (0.6%). 5 out of them (45.4%) had a spontaneous pneumothorax. Four of the patients were on volume control ventilation, with a tidal volume (TV) of 6 to 8 ml/kg and positive end-expiratory pressure (PEEP) ranging from 7 to 12, while one was spontaneously breathing on a continuous positive airway pressure (CPAP) of 10mmHg. (Table 5).

Table 5: Mechanism of Pneumothorax and Mode of Ventilation.

Sr no.	Mechanism of pneumothorax	Numbers and Percentages	Mode of non-invasive ventilation	Numbers and percentages
1	Spontaneous	5(45.45%)	BiPAP	2(18.18%)
2	Post ventilation	6(54.54%)	SFM	2(18.18%)
3			HFNC	1(9.09%)

In our study, 5 patients (45.4%) who developed pneumothorax were on non-invasive ventilation (NIV). Out of these 5 patients, 2 patients (40%) were on SFM, 2 patients (40%) were on bilevel positive airway pressure (BiPAP) and 1 (20%) on high flow nasal cannula (HFNC). (Table 5).

All patients with pneumothorax were treated with steroids and antibiotics. 9 patients were started on anticoagulant therapy and 8 patients received anti-virals. 2 patients also received monoclonal antibodies as part of treatment. (Table 6).

Table 6: Treatment Modalities.

Sr no.	Treatment administered	Numbers and percentages
1	Antivirals	8(72.72%)
2	Antibiotics	11(100%)
3	Anticoagulants	9(81.81%)
4	Steroids	11(100%)
5	Monoclonal antibodies	2(18.18%)

3 of the patients survived while the remaining 8 succumbed to the fatal disease. (Table7).

Table 7: Outcomes in Patients with Pneumothorax.

Sr No.	Outcome	Numbers and Percentages
1	Survived	3(27.27%)
2	Succumbed	8(72.72%)

Discussion

Pneumothorax refers to air getting entrapped in the pleural space which can either be spontaneous or following trauma. [12]. Pneumothorax can also be classified as primary, secondary, iatrogenic (pacemaker insertion, thoracic surgeries) or following blunt/penetrating trauma. [12]. Diseased lung causes secondary pneumothorax whereas primary pneumothorax occurs in generally healthy people without an underlying lung pathology. [13]. In pneumothorax, loss of intrapleural negative pressure causes the lung to collapse partially or impair ventilation, oxygenation or both. The clinical presentation varies from being asymptomatic to life-threatening. [13]. Pneumothorax is a surgical emergency; prompt identification and management are important for a good prognosis. [12,13].

The primary risk factor for spontaneous pneumothorax (SP) is always an underlying lung pathology of which chronic obstructive pulmonary disease with emphysema outscores others such as tuberculosis, smoking, trauma, lung malignancy, Cystic fibrosis, alpha-1 antitrypsin deficiency, HIV associated Pneumocystis pneumonia and other lung diseases. [14-16]. Tall and thin built males in the age group of 10-30 years are known to be at risk for the development of primary spontaneous pneumothorax. [17]. Spontaneous pneumothorax and pneumomediastinum unrelated to intubation or positive pressure ventilation have been reported in various infections such as influenza, pneumocystis jirovecii pneumonia (PCP), herpes simplex, staphylococcus aureus pneumonia, cytomegalovirus, influenza bronchiolitis and severe acute respiratory syndrome (SARS). [18-23]. Other predisposing factors include asthma, corticosteroids, respiratory irritants and other anatomical abnormalities such as tracheomalacia. [24-27].

Development of bullae in otherwise normal lung parenchyma is seen in bullous lung disease. [28] Risk factors for the development of bullae include smoking, pulmonary sarcoidosis, alpha-1 antitrypsin, alpha-1 anti-chymotrypsin deficiency, connective tissue disorders (Marfan's and Ehlers-Danlos syndrome), fibreglass exposure and addiction to drugs (marijuana). [29,30]. In COVID-19, sudden respiratory compromise in otherwise stable patients has been reported. The most prevalent cause for this sudden worsening was a pulmonary embolism, followed by pneumothorax as reported by Shaikha D Al-Shokri et al. [31, 32]. Cough, a common symptom of COVID-19 pneumonia poses an increased risk of spontaneous pneumothorax due to increased intrapulmonary pressure especially in the presence of underlying alveolar damage due to inflammation, ischemic parenchymal damage and other pleural abnormalities. [33-35]. Intense coughing can increase the intrathoracic pressure rapidly to up to 300mmHg. [36]

COVID-19 pneumonia is characterized by overwhelming inflammation and steroids are often recommended for reducing inflammatory responses and is thus a potential strategy for reversing progression in acute respiratory distress syndrome (ARDS). [37]. Steroid use in connective tissue disorders has been seen to weaken the pulmonary interstitial tissue causing an alveolar air leak. [38]. Corticosteroid therapy causes delayed wound healing in fragile lung tissue and leads to the formation of bullae and subsequent pneumothorax through the check valve mechanism. [39]. Even though pneumothorax is implicated in chronic

Steroid use, a previous study describes a COVID-19 patient developing pneumothorax after just 6 days of steroid use from the time of hospitalization. [40]. In patients with SARS and pneumothorax, administration of methylprednisolone affected lung healing and the presence of a higher peak serum LDH and peripheral leukocyte count was postulated to depict a greater extent of lung injury, thus raising the risk of pneumothorax. [41].

COVID-19 data from Wuhan, China showed that obese patients had more severe illnesses and increased mortality. [42]. Studies have found obesity (BMI>=30kg/m2) to be an independent risk factor for pulmonary oedema, diffuse alveolar damage (DAD) and alveolar-capillary hemosiderosis. [43]. One can postulate that obese COVID-19 patients who are at risk for DAD are also at higher risk for developing SPM. Studies have demonstrated COVID-19 viral entry and cellular injury via angiotensin-converting enzyme -2 (ACE-2) receptor into target cells including surfactant-producing type II pneumocytes. [44]. The dysregulation of surfactant production contributes to the development of subcutaneous emphysema (SE) and pneumomediastinum from impaired lung compliance. The upregulation of ACE-2 expression found in chronic hypertension and diabetes mellitus may potentially explain the increased viral load in the population, leading to increased morbidity in COVID-19. [45]. COVID-19 infection can cause severe pneumonia leading to ARDS which is radiographically diagnosed by ground-glass opacities forming consolidative changes and at later stages to fibrotic changes. [7,4]. COVID 19 causes ischemic lung parenchymal damage by activation of inflammatory markers and fibroblasts precipitating fibro-myxoid exudates promoting pulmonary cyst formation. [46,29]. Development of severe intrapulmonary strain due to increased respiratory effort and persistent bouts of cough result in rupture of the alveolar cysts. [47]. Severe lung injury and diffuse alveolar damage contribute to the mechanism of spontaneous pneumothorax complicating severe acute respiratory distress syndrome. [41]. The rupture of alveoli secondary to diffuse alveolar damage as seen in COVID-19 may cause pulmonary interstitial emphysema (PIE), as is seen with neonates on ventilatory support. [48]. Hyperactive and dysregulated immune response known as cytokine storm syndrome leads to a hyperinflammatory form of ARDS which is Associated with critical illness and increased mortality in COVID-19 pneumonia. [49-51]. Hyperferritinemia, haemodynamic instability and multiorgan failure is now recognized as being the main cause of the severity of SARS-CoV-2 infection. [52]. This leads to weakening of bronchial walls causing edema, vascular congestion and microthrombi contributing to the rupture of preexisting bullae leading to pneumothorax. [29].

Laboratory evaluation has a predictive value to identify potential risk factors for spontaneous pneumomediastinum (SPM). Levels of cell death due to plasma membrane damage can be reflected by Lactate dehydrogenase (LDH). In the SARS outbreak, higher peak LDH was associated with SPM as compared with those without SPM (mean 863 U/L Vs 583 U/L). [53]. In the early phase of COVID-19 infection, leukopenia, lymphocytopenia, high level of CRP, high D-dimer, prolonged PT, and high levels of fibrinogen have been reported. [54,55]. A similar trend was noted in our study with the mean Serum LDH level being 825U/L. D-Dimer, total counts and CRP levels were also noted to be high in patients who developed pneumothorax. A study by Chen G et al reported that ferritin level was higher than 800mcg/L in 100% of patients with severe COVID-19 infection. [56]. It has also been reported that serum ferritin of more than 400mcg/L is a risk factor for progression to severe disease in a study by Ji D et al. [57]. The mean Serum ferritin level in our study was 844.5mcg/L

The hallmarks of the virus characterized by CT are bilateral interstitial infiltrates, ground-glass opacity (GGO) patterns, multiple lobar and subsegmental consolidations and air bronchograms. [58,10]. Features like pleural or pericardial effusions, cavitary lesions, bronchiectasis along uncommon features of pneumomediastinum and pneumothorax were also reported. [10,11,59,60]. CT remains the most effective method to detect lung abnormalities and estimate the evolution of the disease. Pneumothorax is a rare radiological finding seen in 1% of 99 patients was reported early in the pandemic by Chen et al. [61].

Severe COVID-19 patients are at high risk for coagulopathy like deep vein thrombosis (DVT), venous thromboembolism (VTE) and possible pulmonary embolism (PE) (25%). [62,63].

Increased D-Dimer, APLA, lactate dehydrogenase with mild to no changes in PT and PTT are seen in COVID-19 coagulopathy. [17,25,26]. Cytokine storm syndrome, DIC, immobilization, hypoxia secondary to excessive lung injury in COVID-19 infection can result in thromboembolic events. [64]. Mechanical ventilation causes overdistension of alveoli, causing the occurrence of a large pressure gradient between the marginal alveoli and lung interstitium, resulting in air leaks to the surrounding bronchovascular sheath (Macklin phenomenon). [65]. This explains how long term ventilation, results in accelerating cyst rupture and tracking air out of pulmonary tissue. [66]. This air traverses to the visceral pleura, mediastinum and cervical soft tissue causing pneumothorax, mediastinal emphysema, pneumomediastinum and cervicofacial subcutaneous emphysema. [34,67,68].

Invasive mechanical ventilation is often required in the treatment of COVID-19 and it appears to be a predominant risk factor for pneumothorax in COVID-19 pneumonia. The incidence of pneumothorax in mechanically ventilated patients is high and even higher in ARDS ranging from 14 to 87%. In our study 11 out of 1825 patients developed a pneumothorax (0.6%). 6 out of them (54.5%) had spontaneous pneumothorax while on mechanical ventilation. Four of the patients were on volume control ventilation, with a TV of 6 to 8 ml/kg and a PEEP ranging from 7 to 12, while one was spontaneously breathing on a CPAP of 10mmHg.The incidence of pneumothorax is seen to increase with the severity and duration of ARDS, duration of ventilation, comorbidities, barotrauma and volutrauma. Aiolfi et al, Yao W et al and Sun R et al reported cases of pneumothorax after mechanical ventilation. [69,3,5]. Sun R also suggested that ventilation using high PEEP may cause the development of pneumothorax, partly through the development of new bullae or rupture of existing bullae or cysts. [5]. Often manoeuvres performed to improve oxygenation such as high PEEP, high tidal volumes and high minute ventilation leads to high peak inspiratory pressures (greater than 40 to 50 cmH2O) alveolar overdistension and pneumothorax. In addition manipulation of the airway (intubation or tracheostomy) may cause alveolar rupture and pneumothorax. [70-72, 34]. Lung protective ventilation strategies such as low-volume and pressure-limited ventilation are essential to minimize barotrauma and volutrauma.

In a previous study, the rate of pneumothorax development was 5.9% in the first 24 hours following initiation of ventilation, and this rate increased to 10.4% after 1 day. [3]. Gattinoni et al, found that the longer the duration of mechanical ventilation in ARDS, the higher the incidence of pneumothorax (87% vs. 30% in those with more than 2 weeks of mechanical ventilation vs. less than 1 week). [73]. In addition, patients with bullae and low lung compliance had higher rates of pneumothorax.

It was interesting to note that patients on NIV (BIPAP, CPAP) and oxygen delivery devices (SFM, HFNC), who are thought to have a low risk of barotrauma and subsequent complications were seen to develop pneumothorax. In our study, 5 patients (45.4%) who developed pneumothorax were on NIV.Out of these 5 patients, 2 patients (40%) were on SFM, 2 patients (40%) were on BiPAP and 1 (20%) on HFNC. The proposed mechanism is that the end-expiratory pressure provided by BiPAP or CPAP increases the pressure gradient between alveoli and the interstitial space, causing alveolar rupture with the extension of air into the mediastinum, pleura, and subcutaneous tissues. That being said the vast majority of patients on NIV do not experience SE or SPM. It has been theorized that extensive airspace disease caused by COVID-19 makes normally low-risk patients susceptible to SE/SPM, perhaps related to the constellation of lung damage, supplemental oxygen, and decreased lung compliance. [74]. Wang et al and Zhou et al presented cases of pneumothorax without invasive ventilation. [40,11].

Wang et al reported a patient who presented with spontaneous pneumothorax, pneumomediastinum and subcutaneous emphysema without invasive ventilation. [40]. A case of pneumothorax in a spontaneously breathing patient was also reported by Zhou et al. [11]. High-flow nasal cannula (HFNC) therapy is an intermediate level of support between conventional oxygen delivery and non-invasive ventilation (NIV) and is capable of delivering up to 100% humidified and heated oxygen at a flow rate of 60L/min and a PEEP of up to 6 cm of water, meeting the increased flow demand and hence reduces the work of breathing in ARDS. [75].

HFNC helps mitigate (patient self-inflicted lung injury) P-SILI by delivering a variable pressure during the respiratory cycle with maximum pressure

In early expiration. This mechanism supplies a PEEP thus promoting alveolar recruitment but also avoids alveolar overdistension despite a high flow. Even though a few cases of possible barotrauma concerning HFNC have been reported in the pediatric population, the incidence of pneumothorax is reported to be as low as 1%. [76,77]. A Multicentric study from the UK comparing non-intubated patients and patients requiring positive pressure ventilation for the development of pneumothorax and pneumomediastinum concluded that both groups were susceptible for pneumothorax and barotrauma alone cannot explain this association. [78].

Conclusion

Having been over 2 years into the pandemic, we now realise that pneumonia is a common sequelae of COVID-19 infection. The mechanism of viral entry and cellular injury through the ACE-2 receptors into target cells as well as the cytokine storm leading to a hyperinflammatory form of ARDS have been delineated. Sudden deterioration of respiratory status in such patients should alert one to the possibility of pneumothorax as the precipitating factor, even in patients not on mechanical ventilation. Institution of lung protecting strategies and early intervention in cases of pneumothorax are thus important in ensuring better outcomes in these patients.

Authors Contribution: Conception and design of work: Rahul George, Vijy Paul Thomas, Data collection: Rahul George, Shalini Miriam Ipe, Data analysis and interpretation: Rahul George, Vijy Paul Thomas, Shalini Miriam Ipe, Joicy Els Jojo, Drafting the article: Rahul George, Shalini Miriam Ipe, Joicy Els Jojo, Critical review of the article: Vijy Paul Thomas, Shalini Miriam Ipe, Final approval of the version to be published: Rahul George, Vijy Paul Thomas, Shalini Miriam Ipe, Joicy Els Jojo

What does this study add to the existing knowledge?

Prompt identification of pneumothorax in COVID 19 pneumonia and timely intervention is necessary to reduce morbidity and mortality. Low tidal volume lung-protective ventilation and the use of non-invasive ventilation for oxygenation remain the cornerstone in the management of COVID pneumonia. It significantly

Decreases iatrogenic complications like VILI (ventilator-induced lung injury) and P-SILI (patient self-inflicted lung injury).
